Background: The naturally occurring $\alpha 5$ (D398N) variant alters smoking behavior, but functional differences have not been detected between $\alpha 3\beta 4\alpha 5$ nAChR harboring these variants.

Results: ACh-induced $\alpha 3\beta 4\alpha 5$ nAChR function is lower when $\alpha 5$ (Asn-398) substitutes for $\alpha 5$ (Asp-398).

Conclusion: The $\alpha 5$ variant-induced change in $\alpha 3\beta 4\alpha 5$ nAChR function may underlie some of the phenotypic changes associated with this polymorphism.

Significance: $\alpha 3\beta 4\alpha 5$ nAChR function may be a useful target for smoking cessation pharmacotherapies.

Genome-wide studies have strongly associated a non-synonymous polymorphism (rs16969968) that changes the 398th amino acid in the nAChR $\alpha 5$ subunit from aspartic acid to asparagine (D398N), with greater risk for increased nicotine consumption. We have used a pentameric concatemer approach to express defined and consistent populations of $\alpha 3\beta 4\alpha 5$ nAChR in *Xenopus* oocytes. $\alpha 5$ (Asn-398; risk) variant incorporation reduces ACh-evoked function compared with inclusion of the common $\alpha 5$ (Asp-398) variant without altering agonist or antagonist potencies. Unlinked $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits assemble to form a uniform nAChR population with pharmacological properties matching those of concatemeric $\alpha 3\beta 4^*$ nAChRs. $\alpha 5$ subunit incorporation reduces $\alpha 3\beta 4^*$ nAChR function after coinjection with unlinked $\alpha 3$ and $\beta 4$ subunits but increases that of $\alpha 3\beta 4\alpha 5$ versus $\alpha 3\beta 4$ -only concatemers. $\alpha 5$ subunit incorporation into $\alpha 3\beta 4^*$ nAChR also alters the relative efficacies of competitive agonists and changes the potency of the non-competitive antagonist mecamylamine. Additional observations indicated that in the absence of $\alpha 5$ subunits, free $\alpha 3$ and $\beta 4$ subunits form at least two further subtypes. The pharmacological profiles of these free subunit $\alpha 3\beta 4$ -only subtypes are dissimilar both to each other and to those of $\alpha 3\beta 4\alpha 5$ nAChR. The $\alpha 5$ variant-induced change in $\alpha 3\beta 4\alpha 5$ nAChR function may underlie some of the phenotypic changes associated with this polymorphism.

Nicotinic acetylcholine receptors (nAChR)² are prototypical members of the ligand-gated ion channel superfamily of neu-

rotransmitter receptors. nAChR exist as a diverse family of molecules composed of different pentameric combinations of homologous subunits derived from at least 17 genes ($\alpha 1$ – $\alpha 10$, $\beta 1$ – $\beta 4$, γ , δ , ϵ). The properties of nAChR are determined by their subunit composition, giving rise to multiple subtypes with a range of overlapping pharmacological and biophysical properties (1). It also has become apparent that different stoichiometries of the same subunits can produce subtypes with distinctly different characteristics, a phenomenon observed in both heterologous and natural expression systems (1–5).

Recently, genome-wide association studies have indicated that single-nucleotide polymorphisms (SNPs) within nAChR subunits can substantially affect nAChR-mediated smoking behavior in humans. Most prominent among these single-nucleotide polymorphisms have been those located in the CHRNA5/CHRNA3/CHRNA4 locus, located on chromosome 15q25, which encodes the $\alpha 5$, $\alpha 3$ and $\beta 4$ subunits of nicotinic receptors. This locus was first associated with nicotine dependence (6). Subsequent studies confirmed associations of single-nucleotide polymorphisms at this locus with heavy smoking (>25 cigarettes smoked daily), Fagerström Test for Nicotine Dependence scores and age dependent severity of nicotine dependence (7–11). One non-synonymous polymorphism (rs16969968), which changes the 398th amino acid from aspartic acid to asparagine (D398N) in the $\alpha 5$ subunit, is particularly strongly associated with greater risk for increased nicotine consumption. Interestingly, variants at this locus also are associated with increased liability for lung cancer (8, 12, 13), and possibly with decreased risk for alcoholism (7, 14) and cocaine dependence (15).

These observations raise the question of what the functional effects of the D398N mutation might be. The $\alpha 5$ subunit can only assemble into functional nAChR when expressed with at least two other subunits (1). In the central nervous system, most $\alpha 5$ subunit expression occurs in combination with $\alpha 4$ and $\beta 2$ subunits (16, 17). Experiments using heterologous expression systems have demonstrated that $\alpha 4\beta 2^*$ nAChR containing $\alpha 5$ subunits harboring the risk (Asn-398) variant have lower function than those that incorporate $\alpha 5$ subunits with the common (Asp-398) variant (11, 18). This provides a mechanism through

which the $\alpha 5$ (D398N) mutation could produce phenotypic effects. Notably, a restricted set of brain regions (most prominently in the habenulopeduncular pathway) express $\alpha 5$ subunits in combination with $\alpha 3$ and $\beta 4$ subunits (19, 20), as often occurs in autonomic $\alpha 3\beta 4^*$ nAChR (21–23). A recent study showed that increased expression of $\alpha 3\beta 4^*$ nAChR in the habenulopeduncular tract of mice increases nicotine aversion, an effect that can be reduced by the introduction and expression of additional $\alpha 5$ (Asn-398) subunits in the same pathway (20). Furthermore, $\alpha 3$, $\beta 4$, and $\alpha 5$ nAChR subunits are commonly expressed in bronchial, epithelial, and lung cancer cells, where nAChR activation by nicotine has been proposed as a mechanism that may increase tumor initiation and/or growth (24). However, heterologous expression studies done to date have not identified functional differences induced by $\alpha 5$ variant incorporation into $\alpha 3\beta 4^*$ nAChR (18, 25).

Other observations may help to explain this discrepancy between *in vitro* observations and *in vivo* phenotypes. It has been shown that $\alpha 3\beta 4$ nAChR can be expressed in multiple stoichiometries, with different functional properties (26–28). Moreover, $\alpha 5$ subunits can “compete” with $\beta 4$ subunits for incorporation into assembled nAChR (29), possibly forcing formation of non-functional nAChR subunit assemblies as “dead end intermediates” (30). Thus, the effect(s) of common $\alpha 5$ (Asp-398) *versus* risk $\alpha 5$ (Asn-398) variant subunit incorporation into $\alpha 3\beta 4^*$ nAChR may be obscured by changes, attendant on *any* $\alpha 5$ subunit incorporation, in the overall level of $\alpha 3\beta 4$ nAChR functional expression and/or the balance of functional stoichiometric isoforms expressed. This complication in experimental interpretation is compounded when various mixtures of nAChR subtypes with specific subunit ratios are expressed from “loose” subunits assembled under host cell, and not investigator, control.

To overcome these difficulties in interpretation, we employed a concatemeric nAChR approach (Fig. 1). Here, nAChR constructs are assembled that encode all five subunits of the desired $\alpha 3\beta 4^*$ nAChR subtypes joined by short peptide linkers. The advantage of this approach is that complex nAChR subtypes can be expressed with native nAChR-like properties and with completely defined subunit ratios and orders of assembly (5, 31). Using concatemeric $\alpha 3\beta 4\alpha 5$ nAChR, we demonstrate that, as is true for $\alpha 4\beta 2^*$ nAChR, incorporation of the $\alpha 5$ (Asn-398) variant reduces maximal acetylcholine-induced function when compared with the $\alpha 5$ (Asp-398) variant. The properties of the defined concatemeric nAChR also were compared with those of $\alpha 3\beta 4^*$ nAChR allowed to assemble freely from loose individual subunits. These comparisons confirmed that concatemeric and freely assembled $\alpha 3\beta 4\alpha 5$ nAChR have essentially indistinguishable pharmacological properties. Interestingly, these comparisons also suggested that loose $\alpha 3$ and $\beta 4$ subunits associate quite differently in the presence or absence of $\alpha 5$ subunits.

EXPERIMENTAL PROCEDURES

Chemicals—All buffer components and pharmacological reagents (acetylcholine, atropine, cytosine, nicotine, and mecamylamine) were purchased from Sigma. Fresh stock drug solutions were made daily and diluted as required.

Constructs for Individual $\alpha 3$, $\beta 4$, and $\alpha 5$ nAChR Subunits—Native human subunit protein sequences for $\alpha 3$, $\beta 4$, and $\alpha 5$ (both Asn-398 and Asp-398 variants) nAChR subtypes were encoded by nucleotide sequences optimized for expression in vertebrate expression systems (synthesized by GeneArt AG; Invitrogen). Optimizations included minimization of high GC content sequence segments, improved codon usage, reduction of predicted RNA secondary structure formation, and removal of sequence repeats and possible alternative start and splice sites. Sequences were subcloned into the pSGEM oocyte high expression vector (a kind gift of Prof. Michael Hollmann; Ruhr-Universitaet, Bochum, Germany).

Concatemeric $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ Constructs—Fully pentameric nAChR concatemers were constructed from human nAChR subunits. cDNAs encoding concatemers were created using the same subunit layout as successfully used to encode high and low agonist sensitivity $\alpha 4\beta 2^*$ nAChR isoforms (5). Subunits were arranged in the order $\beta 4$ - $\alpha 3$ - $\beta 4$ - $\alpha 3$ -X, where X was either $\beta 4$, $\alpha 3$, $\alpha 5$ (Asp-398) or $\alpha 5$ (Asn-398); Fig. 1A. Kozac and signal peptide sequences were removed from all subunit sequences with the exception of subunits expressed in the first position of the concatemer. As previously demonstrated, the initial β - α subunit protein pairs of the constructs will assemble to form an orthosteric binding site between the complementary (–) face of the initial $\beta 4$ subunit and the principal (+) face of the following $\alpha 3$ subunit (4). The assembled $\alpha 3\beta 4^*$ nAChR concatemers thus contain orthosteric agonist binding pockets at the $\beta 4$ (–)/(+) $\alpha 3$ interfaces between the first and second and between the third and fourth subunits (5). As for individual subunits, native human subunit protein sequences were encoded by nucleotide sequences optimized for expression in vertebrate expression systems (synthesized by GeneArt AG). Optimizations fell in the same categories as those previously described. Subunits were linked by alanine-glycine-serine (AGS) repeats designed to provide a complete linker length (including the C-terminal tail of the preceding subunit) of 40 ± 2 amino acids. At the nucleotide level, linker sequences were designed to contain unique restriction sites that allow easy removal and replacement of individual $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits (Fig. 1A). Sequences of all subunits together with their associated partial linkers were confirmed by DNA sequencing (Geneart AG). Each concatemer was subcloned into the pSGEM oocyte high expression vector. Correct assembly of the concatemers into the expression vector was verified by restriction digest (Fig. 1, A and B). Additionally, concatemers were digested with *ScaI* to further diagnose the stoichiometry of each construct (* as indicated; Fig. 1B).

RNA Synthesis—Plasmids containing single $\alpha 3$, $\beta 4$, or $\alpha 5$ (Asn-398 and Asp-398 variants) nAChR subunits or $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ concatemeric constructs were linearized with *NheI* (2 h at 37 °C) and treated with proteinase K (30 min at 50 °C). cRNAs were transcribed using mMessage mMachine T7 kit (Applied Biosystems/Ambion, Austin, TX). Reactions were treated with TURBO DNase (1 unit for 15 min at 37 °C), and cRNAs were purified using Qiagen RNeasy Clean-up kit (Valencia, CA). cRNA purity was confirmed on a 1% agarose gel (Fig. 1B), and preparations were stored at –80 °C.

FIGURE 1. Linked (concatemeric) subunit design of $\alpha 3\beta 4\alpha 5$ receptors. A, shown is a schematic illustration of (from top to bottom) $\beta 4\alpha 3\beta 4\alpha 3\beta 4$, $\beta 4\alpha 3\beta 4\alpha 3\alpha 3$, $\beta 4\alpha 3\beta 4\alpha 3\alpha 5(\text{Asp-398})$, and $\beta 4\alpha 3\beta 4\alpha 3\alpha 5(\text{Asn-398})$ constructs. Each construct is flanked with Ascl and EcoRV restriction sites (5' and 3', respectively; indicated by gray circles) for subcloning into high expression oocyte vectors. Kozac and the $\beta 4$ signal peptide (SP) were retained only for the 1st position. Flanking each subunit position are unique restriction sites (indicated by gray circles) used in concatemer design (for example, Ascl and XbaI used in exchanging nAChR subunits at position 1; XbaI and AgeI sites were used in exchanging nAChR subunits at position 2; etc.). Concatemers varied in composition only at position 5, containing either the $\beta 4$, $\alpha 3$, or two naturally occurring variants of the $\alpha 5$ nAChR subunit (aspartic acid (Asp-398) or asparagine (Asn-398)). Stop codons (SC) were added at the 3' end of subunit position 5. The number of AGS repeats flanking each subunit is listed below each linker region. B, shown is stoichiometry of $\beta 4\alpha 3\beta 4\alpha 3\beta 4$, $\beta 4\alpha 3\beta 4\alpha 3\alpha 3$, $\beta 4\alpha 3\beta 4\alpha 3\alpha 5(\text{Asp-398})$, and $\beta 4\alpha 3\beta 4\alpha 3\alpha 5(\text{Asn-398})$ constructs. Concatemers form pentameric receptors by joining the positive interface of the nAChR subunit at position 1 (P1) and the negative interface of position 5 (P5). Restriction digest (below each schematic) using unique restriction sites (as mentioned above) was used to verify each subunit within its respective position (P1-P5). An additional restriction digest (*) using ScaI was performed to diagnose correct subunit composition and order. M, molecular mass markers.

Oocyte Preparation and RNA Injection—Methods of oocyte isolation and processing for receptor expression have previously been described (32, 33) but were modified as follows. Lobes were digested with 0.75 units/ml Liberase™ (Roche Applied Science), and oocytes were incubated at 13 °C. The tips of pulled glass micropipettes were broken to achieve an outer diameter of ~40 μm (resistance of 2–6 milliohms), and pipettes were used to inject 20–60 nl containing 10 ng of cRNA/oocyte.

Expression of $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ Constructs in *Xenopus* Oocytes—Seven days after injection, *Xenopus* oocytes expressing loose $\alpha 3$ and $\beta 4$ with or without $\alpha 5$ (Asn-398 and Asp-398

variants) subunits from individual cRNAs at the indicated ratios or $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ concatemers were voltage-clamped at -70 mV with an Axoclamp 900A amplifier (Molecular Devices, Sunnyvale, CA). Recordings were sampled at 10 kHz (low-pass Bessel filter, 40 Hz; high pass filter, DC), and the resulting traces were saved to disk (Molecular Devices Clampex v10.2). Data from oocytes with leak currents (I_{leak}) > 50 nA were excluded from recordings. Known nAChR agonists and antagonists were applied using a 16 channel, gravity-fed, perfusion system with automated valve control (AutoMate Scientific, Inc.; Berkeley, CA). All solutions contained atropine sulfate (1.5 μM) to ensure that muscarinic responses were not recorded.

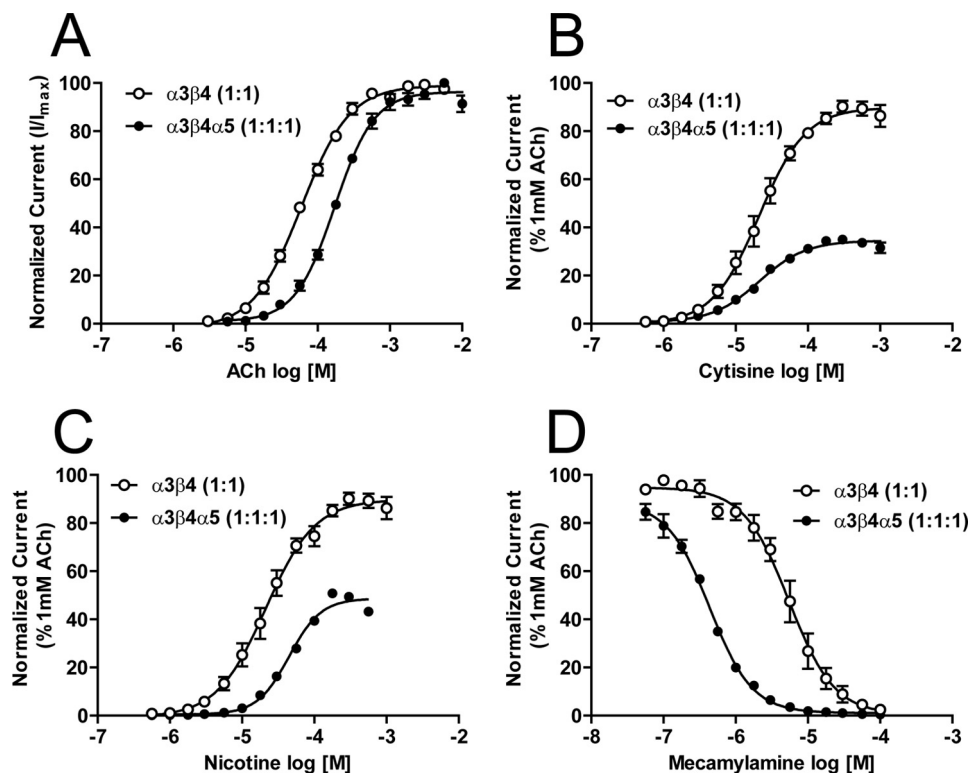

FIGURE 2. Concentration response profiles for $\alpha 3\beta 4\alpha 5$ nAChR expressed as loose subunits. Oocytes injected with RNA for $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits in a 1:1 or 1:1:1 ratio were perfused with nAChR agonists acetylcholine ($10^{-5.5}$ to 10^{-2} ; $n = 6$) (A), cytisine ($10^{-6.25}$ to $10^{-2.5}$; $n = 6$) (B), nicotine ($10^{-6.25}$ to 10^{-2} ; $n = 6$) (C), or the $\alpha 3\beta 4$ nAChR antagonist mecamylamine (10^{-8} to 10^{-4} ; $n = 6$) (D). Data points represent averages (\pm S.E.). Differences in drug potency and efficacy between groups were analyzed using one-way ANOVA with Tukey's post hoc comparison (see "Experimental Procedures").

Oocytes-expressing loose subunits and/or concatemeric $\alpha 3\beta 4\alpha 5$ nAChR were perfused with receptor agonist (e.g. ACh, cytisine, and nicotine) or antagonist (e.g. mecamylamine) for 5 s with 60 s washout times between each subsequent application of drug.

Data Analysis— EC_{50} or IC_{50} values and peak current amplitudes (I_{max}) were determined from individual oocytes. All stimulation protocols began with stimulation by a maximally efficacious dose of ACh (1 mM). This ensured that oocytes were indeed expressing functional nAChR before we did further recording, and it provided an internal control response for each oocyte. Relative agonist efficacies were calculated by comparison to this internal ACh control response. EC_{50} and IC_{50} values were determined through non-linear least squares curve-fitting (GraphPad Prism 4.0, GraphPad Software, Inc., La Jolla, CA) using unconstrained, monophasic logistic equations to fit all parameters, including Hill slopes. Additional normalization was used to compare absolute agonist efficacy between the concatemeric nAChR constructs. As for the nAChR expressed from loose subunits, all peak current response data were collected at 7 days post-injection. Function produced by oocytes expressing ($\alpha 3\beta 4$) $_2\alpha 5$ (Asp-398) concatemers was chosen as the internal reference point for each batch of injected oocytes, as $\alpha 5$ (Asp-398) is the more-common variant. Responses to 1 mM ACh, which is a maximally effective concentration for all of the constructs studied here, were measured. The mean function produced by oocytes injected with ($\alpha 3\beta 4$) $_2\alpha 5$ (Asp-398) concatemers on each experimental day was used to normalize all of the data collected on that day. All four concatemeric constructs

were tested in each experiment. In this way, any residual batch-to-batch oocyte variation could be accounted for.

EC_{50} and IC_{50} values are presented as the mean \pm 95% confidence interval (CI). Data were analyzed using Student's *t* test to compare pairs of groups or by one-way or two-way ANOVA and Tukey's multiple comparison test to compare the means of three or more groups (PRISM, GraphPad Software, Inc.).

RESULTS

Introduction of the $\alpha 5$ Subunit Produces $\alpha 3\beta 4^*$ Receptors with Distinct Pharmacological Responses—In an initial experiment to assess if co-injection of $\alpha 5$ subunits altered functional responses of $\alpha 3\beta 4^*$ nAChR, oocytes were injected with equal amounts of $\alpha 3$ and $\beta 4$ RNA (1:1 injection ratio) or with equal amounts of $\alpha 3$, $\alpha 4$, and $\alpha 5$ RNA (1:1:1 injection ratio). The concentration-response profiles of the resulting nAChR populations are illustrated in Fig. 2. The introduction of $\alpha 5$ significantly decreased ACh potency at the $\alpha 3\beta 4^*$ nAChR population (Fig. 2A; from 59 μ M (CI, 54–65 μ M) to 172 μ M (CI, 158–187 μ M; $p < 0.05$)) and approximately halved the maximum ACh-induced nAChR function (data not shown due to normalization in Fig. 2). In contrast, the introduction of $\alpha 5$ had no effect on cytisine potency at $\alpha 3\beta 4^*$ nAChR (Fig. 2B; mean $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ EC_{50} values, 21 μ M (CI, 18–24.8 μ M) and 20.5 μ M (CI, 17.7–24 μ M), respectively; $p > 0.05$). However, the addition of $\alpha 5$ subunits significantly reduced relative cytisine efficacy when compared with the internal, maximally effective, 1 mM ACh control (Fig. 2B; $\alpha 3\beta 4$ (1:1) = $90.0 \pm 1.9\%$ and $\alpha 3\beta 4\alpha 5$ (1:1:1) = $34.1 \pm 0.7\%$, $p < 0.05$). The $\alpha 3\beta 4$ -only nAChR population also

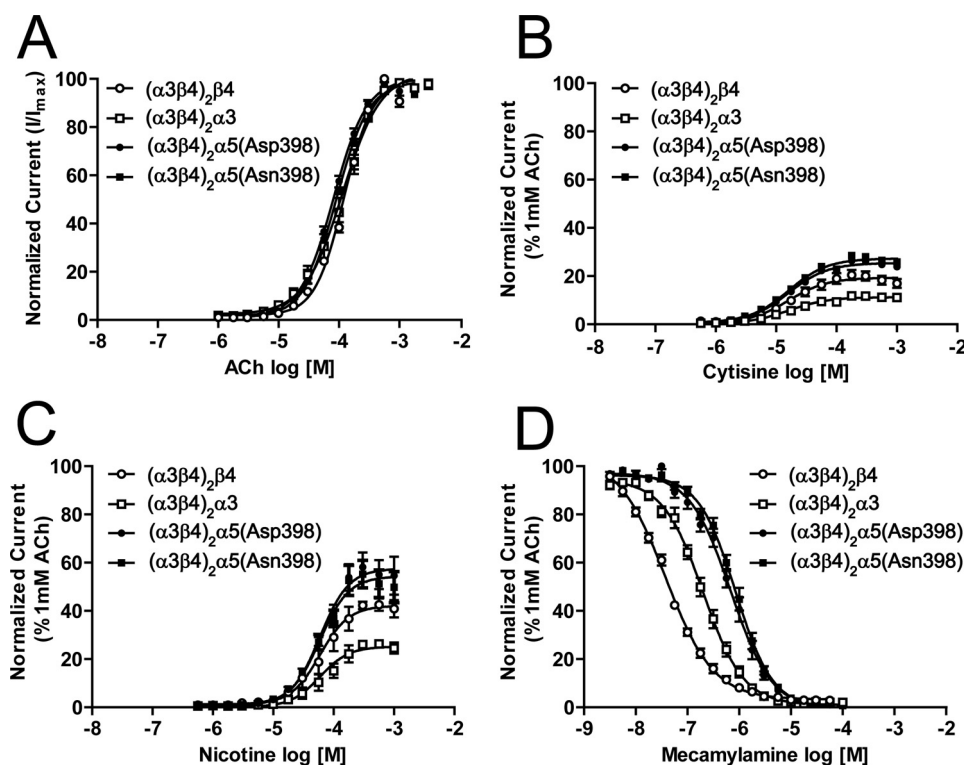

FIGURE 3. Positional effects and functional sensitivity of concatenated $\alpha 3$, $\beta 4$, $\alpha 5(\text{Asp-398})$ and $\alpha 5(\text{Asn-398})$ nAChR subunits. Concentration response curves were generated for linked $\alpha 3\beta 4$ nAChR containing $\beta 4$ at position 5 (open circles), $\alpha 3$ at position 5 (open boxes), $\alpha 5(\text{Asp-398})$ variant at position 5 (filled circles), and $\alpha 5(\text{Asn-398})$ variant at position 5 (filled boxes). Concentration response curves were generated for known $\alpha 3\beta 4$ nAChR agonists acetylcholine ($(\alpha 3\beta 4)_2\beta 4$; $n = 16$; $(\alpha 3\beta 4)_2\alpha 3$; $n = 11$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$; $n = 17$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$; $n = 17$) (A), cytosine ($(\alpha 3\beta 4)_2\beta 4$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 3$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$; $n = 10$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$; $n = 10$) (B), and nicotine ($(\alpha 3\beta 4)_2\beta 4$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 3$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$; $n = 8$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$; $n = 8$) (C). D, concentration response curves were also obtained using the $\alpha 3\beta 4$ antagonist, mecamylamine ($(\alpha 3\beta 4)_2\beta 4$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 3$; $n = 6$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$; $n = 8$; $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$; $n = 8$). Data points represent averages (\pm S.E.). For cytosine, nicotine, and mecamylamine, comparisons were made by normalizing current responses as % 1 mM ACh (see "Experimental Procedures"). Differences in drug potency and efficacy between groups were analyzed using one-way ANOVA with Tukey's post hoc comparison (see "Experimental Procedures").

differed slightly from the $\alpha 3\beta 4\alpha 5$ population in sensitivity to nicotine (21 μM (CI, 18–26 μM) to 45 μM (CI, 40–51 μM) respectively; $p < 0.001$). Similar to the situation with cytosine, introduction of the $\alpha 5$ subunit also reduced the relative efficacy of nicotine (% of internal ACh control per oocyte = $89.8 \pm 2.2\%$ for $\alpha 3\beta 4$ -nAChR compared with $48.7 \pm 1.2\%$ for $\alpha 3\beta 4\alpha 5$ -nAChR; $p < 0.001$). Most strikingly, introduction of the $\alpha 5$ subunit increased the sensitivity of $\alpha 3\beta 4^*$ nAChR to the non-competitive antagonist mecamylamine by more than an order of magnitude ($\alpha 3\beta 4$ -only $\text{IC}_{50} = 5.5 \mu\text{M}$ (CI, 4.4–6.7 μM); $\alpha 3\beta 4\alpha 5$ $\text{IC}_{50} = 0.40 \mu\text{M}$ (CI, 0.38–0.49 μM); $p < 0.0001$).

Effects of Common (Asp-398) and Risk (Asn-398) Variant $\alpha 5$ Subunit Integration into Concatenated $\alpha 3\beta 4$ Receptors—As noted in the introduction, $\alpha 5$ subunits could potentially affect nAChR function in a variety of ways. These could include "competition" with $\beta 4$ subunits for incorporation into assembled nAChR (29) and/or trapping as dead end intermediates of subunits that might otherwise assemble into functional nAChR (30). Self-assembly of individual nAChR subunits could also result in mixed populations of $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ nAChR subtypes, possibly in proportions that vary between individual oocytes. To remove these confounds, we designed pentameric concatemers that enforce precise subunit ratios and assembly orders. The resulting constructs encoded functional nAChR as $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$ and $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$ forms. We also produced concatemers as $(\alpha 3\beta 4)_2\beta 4$ and $(\alpha 3\beta 4)_2\alpha 3$ isoforms

for comparison to concatemers containing $\alpha 5$ subunits. These constructs are displayed schematically in Fig. 1A.

No significant differences in agonist sensitivity (EC_{50}) were observed among concatemers when $\beta 4$, $\alpha 3$, or $\alpha 5$ nAChR subunits were present in the 5th pentameric position (Fig. 3A; $p > 0.05$). In fact, EC_{50} values for multiple agonists were similar across each of the concatemeric constructs and to those measured for $\alpha 3\beta 4\alpha 5$ nAChR assembled from individual subunits at 1:1:1 cRNA ratios (Fig. 3A–C, Table 1; ACh, $p > 0.05$; cytosine, $p > 0.05$; nicotine, $p > 0.05$).

Cytosine consistently demonstrated partial agonism across the concatemeric $\alpha 3\beta 4^*$ nAChR constructs (Fig. 3B). The efficacy of cytosine (normalized to responses to 1 mM ACh) was indistinguishable between $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$ and $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$ concatemers (25.5 ± 0.6 to $27.3 \pm 0.5\%$; respectively; $p > 0.05$). However, cytosine efficacy was significantly reduced at $(\alpha 3\beta 4)_2\beta 4$ tethered pentamers (Fig. 3B; $19.1 \pm 0.8\%$; $p < 0.001$) and still further at $(\alpha 3\beta 4)_2\alpha 3$ constructs (Fig. 3B; $6.0 \pm 0.3\%$; $p < 0.001$). Similarly, nicotine consistently demonstrated partial agonism across the set of concatemeric $\alpha 3\beta 4^*$ nAChR constructs but evoked progressively weaker responses (as a % of 1 mM ACh control responses) in oocytes expressing $(\alpha 3\beta 4)_2\alpha 5(\text{Asp-398})$ ($57.4 \pm 2.7\%$) or $(\alpha 3\beta 4)_2\alpha 5(\text{Asn-398})$ ($53.5 \pm 2.5\%$) assemblies as opposed to $(\alpha 3\beta 4)_2\beta 4$ ($43.3 \pm 2.6\%$) or $(\alpha 3\beta 4)_2\alpha 3$ ($26.6 \pm 1.7\%$) concatemers (Fig. 3C; latter two reductions $p < 0.001$). Overall, the

TABLE 1

Pharmacological parameters calculated from concatemeric $\alpha 3\beta 4^*$ nAChR and from $\alpha 3\beta 4\alpha 5$ nAChR expressed from loose subunits

Oocytes injected with RNA encoding either concatenated $\alpha 3\beta 4^*$ nAChR or single $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits in a 1:1:1 ratio were perfused with the nAChR agonists acetylcholine (10^{-6} to 10^{-2} M), cytosine ($10^{-6.25}$ to 10^{-3} M), nicotine ($10^{-6.5}$ to $10^{-3.5}$ M), or the nAChR antagonist mecamylamine ($10^{-7.5}$ to 10^{-4} M). Data are presented as the mean \pm S.E., with numbers of individual oocytes tested (n) as indicated. * denotes concatemeric constructs.

presence of an $\alpha 5$ subunit in the concatemers resulted in expression of nAChR with increased partial agonist efficacy by cytosine and nicotine compared with that for actions at non- $\alpha 5$ $\alpha 3\beta 4^*$ concatemeric nAChR.

In contrast, the potency of the non-competitive antagonist mecamylamine decreased significantly on the order $(\alpha 3\beta 4)_2\beta 4 > (\alpha 3\beta 4)_2\alpha 3 > (\alpha 3\beta 4)_2\alpha 5$ (Fig. 3D, Table 1; $p < 0.0001$). However, no significant differences in IC₅₀ values were observed between $(\alpha 3\beta 4)_2\alpha 5(D398)$ and $(\alpha 3\beta 4)_2\alpha 5(N398)$ concatemers ($p > 0.05$). Again, the mecamylamine IC₅₀ values recorded from $\alpha 3\beta 4\alpha 5$ nAChR were very similar regardless of whether these nAChR were assembled from individual subunits or from concatemeric constructs (see last three lines of Table 1).

Only Intact nAChR Concatemers Contribute to Recorded Function—In some cases, the covalent linkers within concatemeric constructs have been observed to break down. This liberates smaller products that can assemble to form functional byproducts (4, 34, 35). To determine if this potential confound was present in our system, the $\alpha 5(V_9S)$ “gain-of-function” mutant was coinjected with either a concatemeric construct $(\alpha 3\beta 4)_2\beta 4$ or with individual $\alpha 3$ and $\beta 4$ nAChR subunits. Assembly of the $\alpha 5(V_9S)$ subunit with either single subunits or abridged concatemers would result in a substantial gain of function (34, 36). Co-expression of $\alpha 5(V_9S)$ with unlinked $\alpha 3$ and $\beta 4$ subunits produced a significant increase in function (peak current amplitude elicited by 1 mM ACh; Fig. 4A). This demonstrates that the $\alpha 5(V_9S)$ subunit can assemble with non-linked subunits as predicted. As previously noted, co-injection of a non-gain-of-function $\alpha 5$ subunit at a 1:1:1 ratio approximately halves $\alpha 3\beta 4^*$ function. This suggests that comparing nAChR function between oocytes injected with $\alpha 3$ and $\beta 4$ subunits at a 1:1 ratio to that after injection with $\alpha 3$, $\beta 4$, and $\alpha 5(V_9S)$ subunits at a 1:1:1 ratio may underestimate the effect of the gain-of-function mutation. In contrast, co-injection of the $\alpha 5(V_9S)$ subunit with the concatemeric construct, even at a 3:1 $\alpha 5(V_9S)$:concatemer ratio, produced no change in function (Fig. 4B). These data demonstrate that at least the great majority of nAChR function arising from injection of the concatemeric construct mRNAs must be mediated by intact, pentameric nAChR concatemers.

Absolute Efficacy Comparisons between $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ and $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ nAChR Concatemers—The studies above describe partial agonist efficacies normalized to ACh. However, we wanted to compare absolute agonist efficacies between constructs containing either the $\alpha 5(Asp-398)$ or $\alpha 5(Asn-398)$ variants. The use of concatemeric constructs

FIGURE 4. $\alpha 3\beta 4\alpha 5$ concatemers are expressed as functional pentamers and are not byproducts of fractional assembly. A, co-injection (1:1:1) of loose $\alpha 3$ and $\beta 4$ nAChR subunits with the $\alpha 5$ gain of function subtype (V_9S) enhances receptor function ($p < 0.01$; $n = 4$ oocytes per group). B, overexpression of the $\alpha 5(V_9S)$ subunit has no effect on $(\alpha 3\beta 4)_2\beta 4$ concatemer function ($n.s.$; $n = 4$ oocytes per group). Panels A and B represent normalized currents (% of $\alpha 3\beta 4$ (1:1) or $\beta 4(p5)$, respectively). Normalized currents were analyzed using one-way ANOVA (see “Experimental Procedures”).

allows these comparisons to be made without uncertainty related to the subunit makeup of the functional receptors. However, efficiency of functional nAChR expression varies across oocyte preparations and as a function of time post-injection. To compensate for this form of variation, we used a batch-to-batch normalization strategy (described in detail under “Experimental Procedures”).

As shown in Fig. 5A, peak ACh responses mediated by $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ concatemers were significantly lower than those evoked by stimulation of $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ concatemers ($p < 0.001$). Thus, although no differences in ACh potency were observed between $\alpha 3\beta 4^*$ nAChR containing the $\alpha 5(Asp-398)$ and $\alpha 5(Asn-398)$ variants (as measured by their EC₅₀ values; see Fig. 3A), significant differences were observed in levels of receptor function (as measured by current magnitudes; Fig. 5A). Similar trends were observed when absolute levels of function were measured in response to maximally effi-

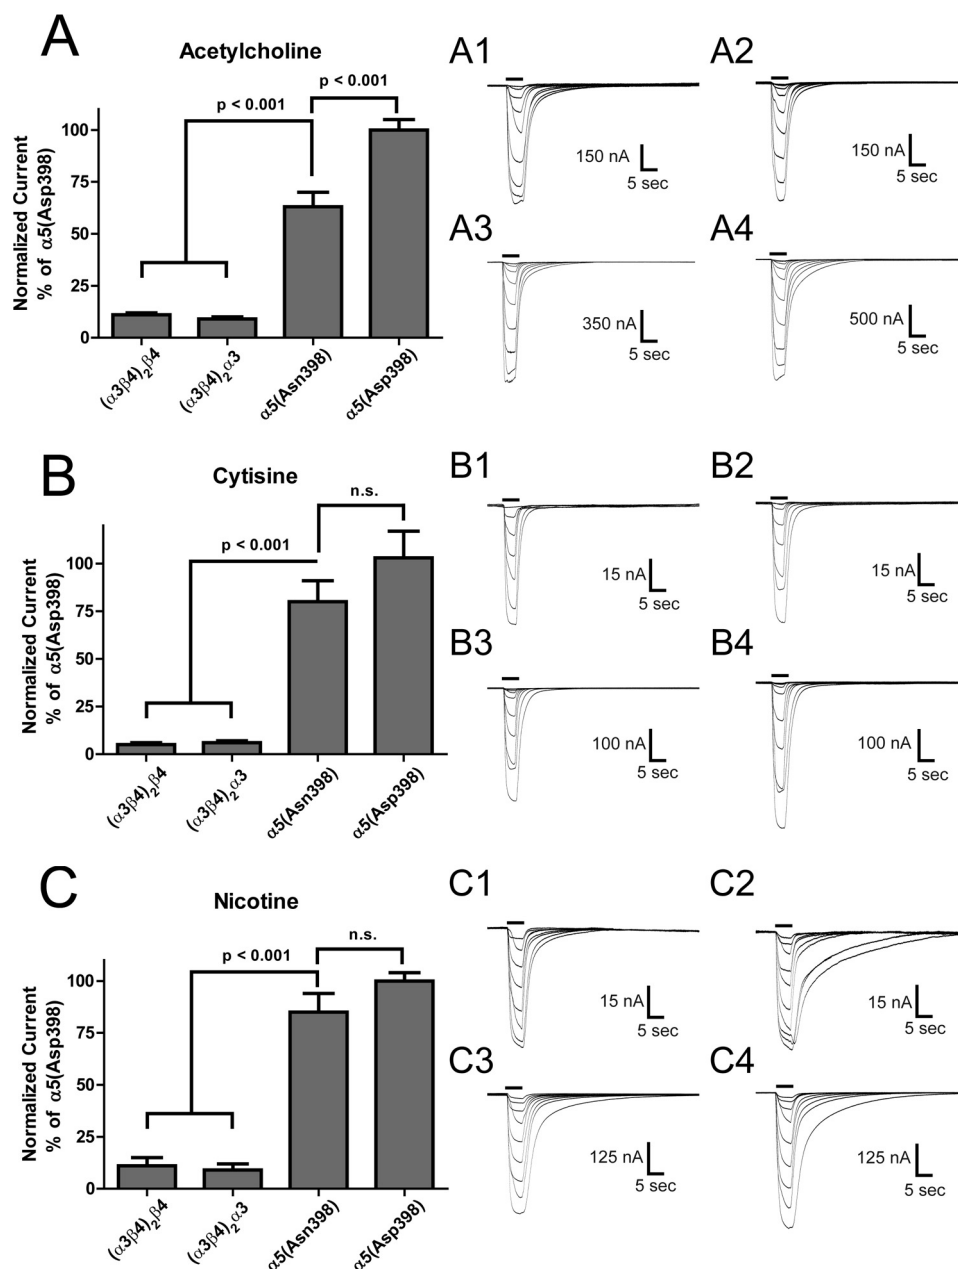

FIGURE 5. Maximum function comparison between $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ and $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ nAChR concatemers. Maximal currents (normalized to $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$; see "Experimental Procedures") were compared between $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ -containing concatemers for acetylcholine (A); panels A1–A4 represent averaged traces for ACh doses (10^{-6} to $10^{-2.25}$) for $(\alpha 3\beta 4)_2\beta 4$ ($n = 16$), $(\alpha 3\beta 4)_2\alpha 3$ ($n = 11$), $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ ($n = 17$), and $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ ($n = 17$), respectively. Peak ACh responses mediated by $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ concatemers were significantly lower than those of evoked by stimulation of $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ concatemers ($p < 0.001$). Maximal currents were also compared between $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ containing concatemers for cytosine (B); panels B1–B4 represent averaged traces for cytosine doses ($10^{-6.25}$ to 10^{-3}) for $(\alpha 3\beta 4)_2\beta 4$ ($n = 6$), $(\alpha 3\beta 4)_2\alpha 3$ ($n = 6$), $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ ($n = 10$), and $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ ($n = 8$), respectively. However, peak cytosine responses mediated by $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ concatemers were not significantly lower than those of evoked by stimulation of $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ concatemers ($p > 0.05$). Additionally, comparisons were made between concatemers for nicotine (C); panels C1–C4 represent averaged traces for nicotine doses ($10^{-6.25}$ to 10^{-3}) for $(\alpha 3\beta 4)_2\beta 4$ ($n = 6$), $(\alpha 3\beta 4)_2\alpha 3$ ($n = 6$), $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ ($n = 8$), and $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ ($n = 8$), respectively. Again, no differences in peak nicotine responses were observed between $(\alpha 3\beta 4)_2\alpha 5(Asn-398)$ -containing concatemers and $(\alpha 3\beta 4)_2\alpha 5(Asp-398)$ -containing concatemers ($p > 0.05$). Maximum responses recorded from $(\alpha 3\beta 4)_2\beta 4$ and $(\alpha 3\beta 4)_2\alpha 3$ nAChR were much smaller than those measured from oocytes expressing either of the $\alpha 5$ variant constructs ($p < 0.001$). Comparisons between groups were analyzed using one-way ANOVA with Tukey's post hoc comparison (see "Experimental Procedures").

cacious concentrations of cytosine (Fig. 5B; 300 μM) or nicotine (Fig. 5C; 300 μM), although in neither case did these apparent differences attain statistical significance ($p > 0.05$).

One of the more striking findings was that for each agonist the maximum responses recorded from $(\alpha 3\beta 4)_2\alpha 3$ or $(\alpha 3\beta 4)_2\beta 4$ nAChR were much smaller than those measured from oocytes expressing either of the $(\alpha 3\beta 4)_2\alpha 5$ variant con-

structs (Figs. 5, A–C; see Table 3). Peak currents were indistinguishable between $(\alpha 3\beta 4)_2\alpha 3$ and $(\alpha 3\beta 4)_2\alpha 4$ nAChR for each agonist. This increased function for $\alpha 5$ -containing concatemers is the opposite of the decreased function observed previously when $\alpha 5$ subunits are co-injected with unlinked $\alpha 3$ and $\beta 4$ subunits. This observation may indicate that enforcing correct assembly of $\alpha 5$ subunits by use of a concatemeric construct

FIGURE 6. **Concentration response profiles for $\alpha 3\beta 4$ -only nAChR expressed as loose subunits.** Oocytes injected with RNA for $\alpha 3$ and $\beta 4$ subunits in a 1:20 or 20:1 ratio were perfused with nAChR agonists acetylcholine (10^{-6} to 10^{-2} ; $n = 4$) (A), cytisine ($10^{-6.25}$ to 10^{-3} ; $n = 4$) (B), nicotine ($10^{-6.5}$ to $10^{-3.5}$; $n = 4$) (C), or the nAChR antagonist mecamylamine ($10^{-7.5}$ to 10^{-4} ; $n = 4$) (D). Data points represent averages (\pm S.E.). Differences in drug potency and efficacy between groups were analyzed using one-way ANOVA with Tukey's post hoc comparison (see "Experimental Procedures").

reduces inefficiencies of assembly or the formation "dead-end intermediates" that have previously been observed when attempting to use self-assembly of individual subunits (30).

Divergent $\alpha 3:\beta 4$ RNA Injection Ratios Produce nAChR with Different Functional Properties—As previously noted, pharmacological parameters measured for $\alpha 3\beta 4\alpha 5$ nAChR were very similar regardless of whether they were expressed from loose subunits or from concatemeric constructs. The same was not true, however, for $\alpha 3\beta 4$ -only subtypes expressed from single subunits injected at a 1:1 ratio or as concatemers (Figs. 2 and 3). It has recently been noted that oocytes injected with different $\alpha 3:\beta 4$ mRNA ratios express $\alpha 3\beta 4$ nAChR populations with differing pharmacological properties (27, 28). By analogy to more extensively studied high and low agonist sensitivity $\alpha 4\beta 2$ nAChR isoforms, it has been speculated that these populations may correspond to $(\alpha 3\beta 4)_2\beta 4$ and $(\alpha 3\beta 4)_2\alpha 3$ stoichiometries (27, 28) as expressed by the concatemeric constructs produced in this study.

The pharmacological properties of nAChR arising from co-injection of $\alpha 3$ and $\beta 4$ subunits at 1:20 and 20:1 ratios are very different (Fig. 6). Oocytes injected with $\alpha 3\beta 4$ in a 20:1 cRNA injection ratio expressed receptors that were less sensitive to ACh than those injected with $\alpha 3\beta 4$ in a 1:20 cRNA injection ratio (Fig. 6A; EC_{50} values of $210 \mu M$ (CI, 199–218 μM) versus $50 \mu M$ (CI, 43–57 μM), respectively; $p < 0.0001$). Cytisine concentration response profiles also differed, yielding lower sensitivity responses for nAChR in oocytes injected with 20:1 $\alpha 3:\beta 4$ subunit cRNAs (Fig. 6B, $EC_{50} = 63 \mu M$; CI, 54–74 μM) when compared with those injected with 1:20 subunit ratios (Fig. 6B,

$EC_{50} = 8.6 \mu M$; CI, 6.7 to 11 μM ; $p < 0.01$). In addition, cytisine efficacy (normalized to 1 mM ACh) was $2.3\times$ greater for oocytes injected with $\alpha 3:\beta 4$ cRNAs at a 20:1 ratio than for oocytes injected with a 1:20 cRNA ratio (Fig. 6B, 266.5 ± 7.5 to $115.3 \pm 2.5\%$, respectively; $p < 0.0001$). Moreover, nicotine EC_{50} values and normalized efficacy values were lower for oocytes injected with $\alpha 3:\beta 4$ subunit cRNAs in a 1:20 ratio than in a 20:1 ratio (Table 2; $25 \mu M$ (CI, 20–33 μM) to $46 \mu M$ (CI, 39–55 μM) respectively, $p < 0.05$). Nicotine was more efficacious for oocytes injected with $\alpha 3:\beta 4$ cRNAs at a 20:1 ratio than for oocytes injected with a 1:20 cRNA ratio (Fig. 6C, $151.9 \pm 5.4\%$ compared with $95.1 \pm 8.2\%$ of 1 mM ACh control, respectively; $p > 0.01$). Finally, oocytes injected with $\alpha 3:\beta 4$ cRNA at a 20:1 ratio were more sensitive to antagonism by mecamylamine than oocytes injected at a 1:20 ratio (Fig. 6D, $0.12 \mu M$ (CI, 0.07–0.18 μM) to $0.89 \mu M$ (CI, 0.8–1.0 μM) respectively, $p < 0.001$).

Overall, the pharmacological properties measured from oocytes injected with $\alpha 3:\beta 4$ cRNAs in a 1:1 or a 1:20 ratio more closely resembled each other than those recorded from oocytes injected at a 20:1 ratio (Table 3). The very similar properties of nAChR arising from 1:1 or 1:20 $\alpha 3:\beta 4$ mRNA injection ratios indicate that the same subunit assembly pattern predominates in both cases. This confirms previous reports that *Xenopus* oocytes injected with 1:1 and 1:9 $\alpha 3:\beta 4$ mRNA ratios express similar $\alpha 3\beta 4$ nAChR populations, whereas high $\alpha 3:\beta 4$ mRNA injection ratios result in expression of a distinctly different $\alpha 3\beta 4$ nAChR isoform (27, 28). However, none of the outcomes observed from oocytes injected with any ratio of $\alpha 3:\beta 4$ mRNAs closely resembled the results obtained from the concatemeric

TABLE 2

constructs or after co-injection of single $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits (Table 1). We conclude that the presence of an $\alpha 5$ subunit or the use of concatemeric constructs results in the assembly of functional nAChR with similar pharmacological properties. These properties are likely the hallmark of assembly into a format containing two ($\alpha 3/\beta 4$) subunit interfaces, with the addition of a fifth subunit in a non-ligand binding role. This conclusion is supported by a very recent study showing similar pharmacological profiles of ($\alpha 3\beta 4$)₂X nAChR assembled from $\alpha 3$ - $\beta 4$ dimeric concatemers with the addition of single $\alpha 3$, $\beta 4$, or $\alpha 5$ subunits (37). Without the constraints imposed by the concatemeric linkers or by the need to integrate a non-ligand binding $\alpha 5$ subunit, it seems possible that $\alpha 3$ and $\beta 4$ subunits are free to assemble into at least two other formats. The relative proportions of the two formats expressed in the *Xenopus* oocyte system can be altered by biasing the $\alpha 3:\beta 4$ nAChR subunit mRNA injection ratio.

DISCUSSION

The pentameric concatemer approach allows accurate and consistent reproduction of complex nAChR subtypes, with complete control over subunit ratios and associations (5, 31, 38, 39). It also allows for mutagenesis of a single subunit within an entire nAChR complex even where multiple copies of the target subunit may be present. These unique advantages were central to the work presented in this study. Using concatemeric $\alpha 3\beta 4\alpha 5$ nAChR, we show that $\alpha 5$ subunit risk variant (Asn-398) incorporation reduces ACh-evoked function when compared with inclusion of the $\alpha 5$ common variant (Asp-398). Coexpression of unlinked $\alpha 3$, $\beta 4$, and $\alpha 5$ subunits enforces assembly of an apparently uniform nAChR population with very similar pharmacological properties to those of concatemeric $\alpha 3\beta 4^*$ nAChR. In addition, either variant of the $\alpha 5$ subunit is capable of reducing the overall amount of $\alpha 3\beta 4^*$ nAChR function after coinjection with non-concatenated $\alpha 3$ and $\beta 4$ subunits. Further observations suggested that removing the constraints imposed by either concatemerization or by co-expression with unlinked $\alpha 5$ subunits allows loose $\alpha 3$ and $\beta 4$ subunits to assemble into at least two further subtypes. These

$\alpha 3\beta 4$ -only subtypes have substantially different pharmacological profiles from each other, from unlinked subunit $\alpha 3\beta 4\alpha 5$ nAChR, and from any of the concatenated $\alpha 3\beta 4$ or $\alpha 3\beta 4\alpha 5$ nAChR.

Critically, the pharmacological properties of $\alpha 3\beta 4\alpha 5$ nAChR expressed using pentameric concatemers were similar to those of the same subtype expressed from unlinked subunits. This finding indicates that the addition of the concatemeric linkers did not noticeably alter nAChR function. It also reinforces further that pentameric concatemers faithfully replicate the ligand sensitivity of the equivalent subunit arrangement when formed from loose subunits. It has been suggested that $\alpha 5$ subunits compete with $\beta 4$ subunits (20, 29), reducing expression of functional $\alpha 3\beta 4\alpha 5$ nAChR, possibly by encouraging the formation of dead-end intermediates that become trapped inside the cell (30). Our observations support this concept. Coinjection of non-concatenated $\alpha 5$ subunit mRNA approximately halved $\alpha 3\beta 4^*$ functional expression in *Xenopus* oocytes compared with injection of loose $\alpha 3$ and $\beta 4$ subunits only (1:1:1 or 1:1 ratios were used; see the legend to Fig. 2). In contrast, if the $\alpha 5$ subunit is forced by concatemerization to assemble only as part of a pentameric nAChR complex, its incorporation substantially increases functional expression (Fig. 5). Together, these observations suggest that a reduction in function is not caused by the incorporation of $\alpha 5$ subunits *per se*. Instead, the presence of loose $\alpha 5$ subunits likely adversely affects the efficiency of unlinked $\alpha 3$ and $\beta 4$ nAChR subunit assembly into functional nAChR.

In contrast, $\alpha 3\beta 4$ -only nAChR expressed from pentameric concatemers had different pharmacological properties from those expressed from loose subunits (Table 1, top two rows, and Table 2). This discrepancy could be explained in several ways. One possibility is that covalent linkers may alter the properties of concatemeric nAChR by constraining structural transitions that are essential for normal function. This concern is mitigated by previous publications (5, 31, 38, 39) indicating that well designed pentameric nAChR concatemers can accurately reproduce the properties of multiple native nAChR subtypes

(which assemble from unlinked subunits). In addition, the linkers in each of the pentameric concatemers used in this study are of the same length and composition; it is unlikely that only the non- $\alpha 5^*$ concatemers used in this study would suffer from linker-induced functional alterations. Furthermore, if the non- $\alpha 5^*$ concatemers were uniquely affected by the presence of the linkers, it would be expected that this would strongly alter agonist potencies and relative efficacies when compared with those of the $\alpha 5^*$ concatemers. This is not the case; the pharmacological parameters measured from all four of the concatemers tested here are strikingly similar. A second possibility is that the covalent linkers within the concatemers might break down. This would release sub-pentameric products that could assemble to form unintended, but functional, byproducts (4, 34, 35). The presence of such degradation products was checked for by coinjection with an $\alpha 5(V_9S)$ mutant subunit. Assembly of this mutant subunit with either single $\alpha 3$ and $\beta 4$ subunits or sub-pentameric concatemers would result in a substantial gain of function (34, 36). No change in function was noted when $\alpha 5(V_9S)$ was co-injected with a concatemeric construct. This confirms that all, or nearly all, of the function in oocytes injected with pentameric nAChR mRNA constructs arises from fully-pentameric concatemeric nAChR. Finally, and most likely, the precise subunit associations imposed by concatemeric constructs may, or may not, correspond to those favored during association of loose subunits. Our data suggest that the $\alpha 3\beta 4\alpha 5$ concatemers accurately reproduce the conformation adopted when the relevant individual subunits assemble freely. However, the same is not true for the $\alpha 3\beta 4$ -only constructs when compared with nAChR assembled from loose $\alpha 3$ and $\beta 4$ subunits. This would indicate that one role of the $\alpha 5$ subunit is to impose a particular subunit composition on $\alpha 3\beta 4^*$ nAChR expressed from loose subunits. If $\alpha 5$ is a true "accessory" subunit (*i.e.* does not interact directly with ligands), this may be unavoidable; a $(\alpha 3\beta 4)_2\alpha 5$ conformation is the only one in which two pairs of $\alpha 3 + \beta 4$ subunits would be available to provide agonist binding pockets and thus to assemble a functional $\alpha 3\beta 4\alpha 5$ nAChR.

The preceding observations raise the question of which nAChR subtype(s) is expressed after coinjection of only $\alpha 3$ and $\beta 4$ subunits. This study confirms prior reports that at least two $\alpha 3\beta 4$ nAChR populations may be formed and that their relative expression levels depend on the molar injection ratio of the subunit mRNAs (1:20 *versus* 20:1). The pharmacology observed in this study matches that reported in other recent publications (27, 28) that used less-extreme injection ratios (1:9 *versus* 9:1 or 1:10 *versus* 10:1). The lack of further changes in observed pharmacology after adoption of more extreme subunit ratios indicates that, as for $\alpha 4$ and $\beta 2$ subunits (2, 40, 41), relatively pure populations of two different $\alpha 3\beta 4$ subunit assemblies are produced at the injection ratios used in this study. The same studies proposed again by analogy to the well-studied $\alpha 4\beta 2$ nAChR that the different nAChR isoforms might correspond to $(\alpha 3\beta 4)_2\beta 4$ and $(\alpha 3\beta 4)_2\alpha 3$ nAChR (27).

Accordingly we constructed $(\alpha 3\beta 4)_2\beta 4$ and $(\alpha 3\beta 4)_2\alpha 3$ concatemers using the same subunit arrangements as used successfully to encode high and low agonist sensitivity pentameric $\alpha 4\beta 2$ nAChR concatemers (5). We initially anticipated that

these concatemers would have similar pharmacological profiles to $\alpha 3\beta 4$ -only nAChR formed after injection of loose $\alpha 3$ and $\beta 4$ subunits at 1:20 and 20:1 ratios, respectively. However, the pharmacology observed after injection of loose $\alpha 3$ and $\beta 4$ subunits at either 1:20 or 20:1 ratios (Fig. 6, Table 2) was strikingly different from the concatemeric " $(\alpha 3\beta 4)_2X$ -type" measurements. The precise arrangements adopted by loose $\alpha 3$ and $\beta 4$ subunits injected at different ratios remain unknown. It certainly seems probable that 1:20 and 20:1 $\alpha 3:\beta 4$ injection ratios may give rise to nAChR with different stoichiometries (27, 28). In addition, as demonstrated for GABA_A receptors, the precise order of subunit incorporation (even for identical subunit stoichiometries) can affect receptor function (42). The emerging awareness that agonist binding to non-canonical nAChR interfaces can strongly affect function underlines this point (5, 41, 43). Determining whether different $\alpha 3:\beta 4$ subunit mRNA injection ratios produce nAChR with different stoichiometries, different arrangements of the same subunit stoichiometries, or both will require a great deal more investigation. The concatemeric pentamer approach is uniquely well suited to addressing this question.

Unlike agonist EC₅₀ values, IC₅₀ values for mecamylamine inhibition were greatly affected by the identity of the fifth subunit in each pentameric concatemer. This suggests that mecamylamine (a non-competitive antagonist) interacts with the resulting nAChR in a position where it can be influenced by the presence of alternate subunits in the fifth, non-agonist-binding position. This sensitivity to $\alpha 3\beta 4^*$ nAChR composition was also evident when comparing mecamylamine IC₅₀ values between $\alpha 3\beta 4$ and $\alpha 3\beta 4\alpha 5$ nAChR expressed from loose subunits (Table 1). These observations indicate that non-competitive ligands may provide the best opportunities to pharmacologically distinguish between different subunit arrangements of $\alpha 3\beta 4^*$ isoforms. Importantly, this category could also include positive allosteric modulators and/or allosteric agonists in addition to non-competitive antagonists. Given the association of $\alpha 5$ subunit variants with a variety of substance abuse behaviors (see introduction), selective manipulation of $\alpha 3\beta 4\alpha 5$ nAChR activity could have valuable therapeutic implications.

Functional effects of the $\alpha 5$ (D398N) mutation are hard to distinguish without using a fully pentameric concatemer approach. The previously described effects of $\alpha 5$ subunits on the efficiency of $\alpha 3\beta 4^*$ nAChR expression and possibly also on subunit associations/assembly could outweigh and obscure the effects of the $\alpha 5$ (D398N) mutation. This could explain previous studies' conclusions that the effects of $\alpha 5$ (Asp-389) incorporation were the same as those of $\alpha 5$ (Asn-389) (18, 25, 37). However, using a pentameric concatemer approach, we were able to compare the function of uniform populations of $(\alpha 3\beta 4)_2\alpha 5$ (Asp-389) *versus* $(\alpha 3\beta 4)_2\alpha 5$ (Asn-389) nAChR. The maximum ACh-induced function produced by $(\alpha 3\beta 4)_2\alpha 5$ (Asp-389) nAChR was significantly greater than that measured for $(\alpha 3\beta 4)_2\alpha 5$ (Asn-389) nAChR (Fig. 5). Increased function for $\alpha 5$ (Asp-398)* *versus* $\alpha 5$ (Asn-398)* nAChR with little difference in pharmacological profile matches previous observations regarding $\alpha 5$ variant incorporation into $\alpha 4\beta 2^*$ nAChR (11, 18).

It appears that, as previously proposed (20), $\alpha 5$ subunit expression may act to modulate the amount of $\alpha 3\beta 4^*$ nAChR function in the habenulopeduncular tract and in other tissues that express $\alpha 3\beta 4\alpha 5$ nAChR. This study indicates that the presence of the $\alpha 5(\text{Asp-398})$ or $\alpha 5(\text{Asn-398})$ variant will impose an additional layer of functional modulation. As noted previously (18), the concentrations of nicotine present in smokers are too low to significantly activate or desensitize $\alpha 3\beta 4\alpha 5$ nAChR. However, the activity induced by synaptic or perisynaptic ACh release onto $\alpha 3\beta 4^*$ nAChR could be strongly affected by the integration of $\alpha 5(\text{Asp-398})$ or $\alpha 5(\text{Asn-398})$ subunits. This in turn could result in compensatory changes either at the neurotransmitter/receptor level or at the circuit activity level, which may explain some of the phenotypic variations attributed to the $\alpha 5(D398N)$ mutation. Given the established role of the habenulopeduncular pathway $\alpha 3\beta 4\alpha 5$ nAChR function in nicotine dependence and aversive behavior (20, 44, 45), it seems likely that selective manipulation of $\alpha 3\beta 4\alpha 5$ function mediated by this subtype could represent a valuable smoking cessation strategy. Our current findings indicate that non-competitive/allosteric compounds may be the most promising category of potential therapeutic agents for such an approach.

Acknowledgment—We thank Minoti Bhakta for technical assistance with concatemer design and construction.
